I have a deck of cards in front of me. I pick one card at random and it is black. How likely is it that the next card is black? What is the probability of picking a black card when the first card was black? There is a lot of hype about negative probabilities and I have questions about how they are actually calculated. It looks like the question I have above can be answered using Bayes theorem. However, I am curious about what calculations in fact lead up to that number. A: If by "black" you mean "black-jack," then the probability of drawing black from a stack of one black-jack and several reds or black cards is $p(\text{black} \mid \text{black on top of deck}) = \frac{5}{52} = 9.6250 \dots \cdot 10^{-4}$. The hyperbolic sine of that number is 0.000115965535991583257 . Using the numerical answer, the probability is $\frac{5}{52} \cdot \frac{\frac{5}{51}}{1 - \frac{5}{52}} = 5.9558 \dots \cdot 10^{-4}$, which agrees with the result. If by "black" you mean "black-jack," then there are 52 possibilities. The probability of picking black is $\frac{5}{52}$, so the probability of picking black from a deck of one black-jack and several reds or black cards is $\frac{5}{52}$.
